Abstract

We present an introductory survey of temporal and dynamic logics: logics for reasoning about how environments change over time, and how processes change their environments. We begin by introducing the historical development of temporal and dynamic logic, starting with the seminal work of Prior. This leads to a discussion of the use of temporal and dynamic logic in computer science. We describe three key formalisms used in computer science for reasoning about programs (LTL, CTL, and PDL), and illustrate how these formalisms may be used in the formal specification and verification of computer systems. We then discuss interval temporal logics. We conclude with some pointers for further reading.

1 Introduction

Mathematical logic was originally developed with the goal of formalising mathematical reasoning – to formalise notions such as truth and proof. One important property of mathematical expressions such as theorems and their proofs is that they are inherently *timeless*: a result such as Fermat’s Theorem is true now, always has been true, and always will be true – irrespective of when it was actually proved. In this sense, mathematical logic was conceived with the goal of developing formal languages for representing a fixed, non-changing world, and the semantics of classical logic reflect this assumption. In the semantics of classical logic, it is assumed that there is exactly one world (called a model), which satisfies or refutes any given sentence. But this limits the applicability of such logics for reasoning about *dynamic* domains of discourse, where the truth status of statements can change over time.

It is of course possible to reason about time-varying domains using classical first-order logic. One obvious approach is to use a two-sorted language, in which we have

one sort for the domain of discourse, and a second sort for points in time. Variables t, t', \dots are used to denote time points, and a binary “earlier than” relation, “ $<$ ” is used to capture the temporal ordering of statements. Using this approach, for example, the English sentence “It is never hot in Liverpool” might be translated into the following first-order formula:

$$\forall t. \neg \text{Hot}(\text{Liverpool}, t)$$

This approach is sometimes called the method of temporal arguments [33], or simply the first-order approach [18]. The advantage of the approach is that no extra logical apparatus must be introduced to deal with time: the entire machinery of standard first-order logic can be brought to bear directly. The obvious disadvantages are that the approach is unnatural and awkward for humans to use. Formulae representing quite trivial temporal properties become large, complicated, and hard to understand. For example, when translated to first-order logic the English sentence “we are not friends until you apologise” becomes something like the following:

$$\begin{aligned} \exists t. [(\text{now} < t) \wedge \text{Apologise}(\text{you}, t)] \wedge \\ \forall t'. [(\text{now} < t' < t) \rightarrow \neg \text{Friends}(\text{us}, t')]. \end{aligned}$$

The desire for logics that are capable of naturally and transparently capturing the meaning of statements such as those above, in dynamic environments, led to the development of specialised *temporal* and *dynamic* logics. This article is intended as a high-level survey of such logics. Contemporary research in temporal and dynamic logics is a huge and very active enterprise, with participation from disciplines ranging from philosophy and linguistics to computer science [22]. Within the latter, it is especially the application of temporal and dynamic logics to verifying the correctness of computer systems that had a huge impact on the field. In an amazing example of technology transfer, this application has transformed purely philosophical logics into industrial-strength software analysis tools [40].

Before taking a look at such recent developments, however, we reflect on the origins of temporal logic, and in particular, the contributions of Arthur Prior.

2 The Origins of Temporal Logic

As we noted in the introduction, in classical logic it is implicitly assumed that formulae are interpreted with respect to a single model. But this inherently static view of logic and its subject matter makes it awkward to apply classical logic to the analysis of everyday sentences such as “Barack Obama will win the election”, since this statement might be true if evaluated now, but false if evaluated next week. It was concerns like this that led Arthur Prior, a philosopher and logician born in New Zealand in 1914, to start working on logics intended to facilitate reasoning about such statements. In Prior’s words [32]: “Certainly there are unchanging truths, but there are changing truths also, and it is a pity if logic ignores these, and leaves it . . . to comparatively

informal dialecticians to study the more dynamic aspects of reality.” Prior’s work, mainly carried out in the 1950s and 1960s, is regarded as the foundation of the area now called temporal and dynamic logic [30, 31].

To analyse sentences such as “Barack Obama will win the election”, Prior proposed the idea of regarding tense as a species of *modality*. He took classical propositional logic with its connectives \vee (for “or”), \neg (“not”), and \rightarrow (“if . . . , then . . .”) and extended it with modal *tense operators*, F and P . In Prior’s notation, Fp stands for “it will be the case that p ” and Pp stands for “it was the case that p ”. In a similar way as in classical logic, one can define other basic tense operators as composed formulae. For example, the expression Gp (read “generally, p ”) is defined as $\neg F\neg p$ (meaning “ p will always be the case”) and Hp (“heretofore, p ”) is defined as $\neg P\neg p$ (meaning “ p has always been the case”). Other temporal operators are also sometimes used, such as $\neg F\neg Fp$ (“ p will be the case again and again”).

Given this set-up, in addition to classical tautologies, (sentences like $p \rightarrow p$, which are true independently of the model under consideration), one should also consider temporal tautologies: formulae using tense operators that are true independently from the truth of its propositional atoms. Priors first axiomatization of temporal tautologies included formulae such as

$$FFp \rightarrow Fp, \quad \text{and} \quad F(p \vee q) \rightarrow (Fp \vee Fq).$$

The first formula, for example, states “if it will be the case that it will be the case that p , then it will be the case that p ”. A less obvious candidate for a temporal tautology is its “converse” $Fp \rightarrow FFp$. A moment’s reflection should convince the reader that the truth of this formula depends on precisely how Fp is interpreted. In other words, to decide whether this formula is a temporal tautology one has to define a formal semantics for the temporal language. Of course, one cannot interpret Prior’s formulae in the static, non-changing models of classical logic. Instead one has to develop models that capture the evolution of reality over time. Leaving aside the question of how a physicist might answer this question, one obvious and mathematically simple approach is to interpret time as a linear sequence of time points:

$$t_0, t_1, t_2, \dots$$

These time points can be naturally interpreted as, say, dates in a calendar. Mathematically, however, we can view the flow of time as the natural numbers \mathbb{N} , ordered by the usual “less than” relation, “ $<$ ”. Many other models of time are also possible, with correspondingly different properties.

Now, in contrast to classical logic, a formula can be true at one time point, and false at another time point. Thus, we obtain a time-dependent notion of truth: a formula might be true when evaluated at t_i and false when evaluated at t_{i+1} . Formally, each time point t_i comes with a truth assignment stating which propositional atoms p are true at t_i . The propositional connectives are interpreted as in classical logic (for example $\phi \wedge \psi$ is true at t_i if, and only if, ϕ and ψ are both true at t_i). Finally,

Fp is true at t_i if, and only if, there exists $j > i$ such that p is true at t_j ;

Pp is true at t_i if, and only if, there exists $j < i$ such that p is true at t_j .

Assuming, for example, that p is true at t_{100} and no other time point, then Fp is true at t_0 . In fact, it is true at all time points between (and including) t_0 and t_{99} , but not at t_{100} nor any time point after t_{100} . Let us check that $FFp \rightarrow Fp$ is true in every time point no matter at which points p is true. To this end, assume that FFp is true at, say, t_n . Then Fp is true at some time point after t_n , say t_m . Similarly, this means that p is true at some time point after t_m , say t_k . But then t_k is a time point after t_n and we obtain that Fp is true at t_n . We have shown that Fp is true at any given time point if FFp is true at that time point. Thus, $FFp \rightarrow Fp$ is true at every time point, independently from p . Note that what we have applied here is the natural assumption that temporal precedence is transitive: if t_k is after t_m and t_m is after t_n , then t_k is after t_n . In contrast, the truth of $Fp \rightarrow FFp$ in this model of time depends on p . For example, assume that p is true at t_5 and no other time point. Then Fp is true at t_4 , but FFp is not true at t_4 : it is not possible to find a time point after t_4 that is before t_5 . In fact, it is not difficult to see that a time model $(T, <)$ with set of time points T and temporal precedence relation $<$ validates $Fp \rightarrow FFp$ if, and only if, it is *dense*: for any two time points $t_1 < t_2$ there is a time point t' such that $t_1 < t' < t_2$. Thus, if we move from the *discrete* time model t_0, t_1, \dots to a *dense* model of time that resembles the rational or real numbers, we obtain new temporal tautologies (and loose others).

This small example illustrates one of the main distinctions between classical and temporal logics: even if the language is fixed and as simple as the basic tense logic with operators F and P , there remains a number of choices to be made with respect to the model used to represent time. Depending on the temporal domain and discourse of interest, one can choose between flows of time that are discrete, dense, or continuous; time can be cyclic or cycle-free; and time can be endless or start with a “big bang”. There are many possibilities, and in the late 1960s and early 1970s it became something of an industry to axiomatize and analyse the temporal tautologies of such time models.

In addition to varying the flow of time, also more tense operators were introduced and investigated. Of particular interest are the binary operators S (for *since*) and U (for *until*) whose semantics is defined as follows:

pUq is true in t if, and only if, there exists $t' > t$ such that q is true in t' and p is true in t'' for all t'' such that $t < t'' < t'$;

pSq is true in t if, and only if, there exists $t' < t$ such that q is true in t' and p is true in t'' for all t'' such that $t' < t'' < t$.

Note that Fp and Pp can be expressed using since and until as

$$Fp = \top Up \quad \text{and} \quad Pp = \top Sp,$$

where \top is a propositional constant standing for a propositional tautology. For axiomatizations of temporal tautologies for languages with operators F , P , S , and U for various time flows see [8].

3 Temporal *versus* Predicate Logic

In our introduction to Prior's basic tense logic, we emphasised that the main difference between classical and temporal logic is time-dependence: in classical logic truth is time-independent, whereas in temporal logic it is not. Under this view, temporal languages are extensions of propositional logic by means of temporal operators. There is, however, a very different and equally important interpretation of temporal logic, namely as a fragment of predicate logic (see [4] for a general discussion of these two different views in modal logic). To achieve this, propositional atoms are identified with unary predicates and complex temporal formulae become predicate logic sentences with exactly one free variable x that ranges over time points. Consider, for example, the sentence “the mail will be delivered”. In Prior's tense logic, this is formalised as Fp , where p stands for “the mail is delivered”. In contrast, in predicate logic one introduces a unary predicate P ranging over time points for “the mail is delivered” and the sentence is formalised as $\exists y(x < y \wedge P(y))$, where $<$ stands for temporal precedence.

To make the connection between temporal and predicate logic precise, consider a flow of time $(T, <)$ which can be, for example, the discrete time flow t_0, t_1, \dots or a copy of the rational or real numbers. A valuation v determines at which time points $t \in T$ an atom p from a given set Φ of propositional atoms is true. Equivalently, we can describe the resulting model by identifying $(T, <, v)$ with the first-order relational model

$$M = (T, <, (p^M \mid p \in \Phi)),$$

where $p^M \subseteq T$ denotes the set of time points at which p is true. Thus, now we regard the $p \in \Phi$ as unary predicates that have as extensions a set of time points. Inductively, we can translate every temporal logic formula ϕ in the language with, say, S and U , as a first-order predicate logic formula $p^\sharp(x)$, where x is a fixed individual variable:

$$\begin{aligned} p^\sharp &= p(x) \\ (\phi \wedge \psi)^\sharp &= \phi^\sharp(x) \wedge \psi^\sharp(x) \\ (\neg\phi)^\sharp &= \neg\phi^\sharp(x) \\ (\phi S\psi)^\sharp &= \exists y(y < x \wedge \psi^\sharp(y) \wedge \forall z((y < z < x) \rightarrow \phi^\sharp(z))) \\ (\phi U\psi)^\sharp &= \exists y(y > x \wedge \psi^\sharp(y) \wedge \forall z((x < z < y) \rightarrow \phi^\sharp(z))) \end{aligned}$$

where y, z are fresh individual variables and $\phi^\sharp(y)$ and $\phi^\sharp(z)$ are obtained from $\phi^\sharp(x)$ by replacing x with y and z , respectively (see [22] for details).

By definition of \cdot^\sharp , we have that a temporal logic formula ϕ is true at a time point t in a model M if, and only if $M \models \phi^\sharp[t]$, where \models is the standard truth-relation of first-order predicate logic. Thus, modulo the translation \cdot^\sharp , we can regard the temporal language with operators S and U as a fragment of first-order predicate logic. The formulae obtained as translations of temporal formulae are, of course, only a tiny subset of the set of all first-order predicate logic formulae (even those with one free variable x using only unary predicates $p \in \Phi$ and the binary predicate $<$). Moreover, for arbitrary time flows, there are many first-order predicate formulae of this form that are *not equivalent* to any translation of a temporal formula. However, a fundamental result proved by Hans Kamp [23] established that, for some important flows of time, every first-order predicate logic formula in the language with unary predicates $p \in \Phi$ and the binary predicate $<$ and having exactly one free variable is indeed equivalent to a temporal formula using since and until. The precise formulation is as follows:

Theorem 1 (Kamp) *Let $(T, <)$ be a flow of time consisting of the natural or real numbers. Then one can construct for every first-order formula $\varphi(x)$ using $<$ and $p \in \Phi$ and with one free variable x , a temporal formula φ^T using the operators S and U such that the following holds for every model $M = (T, <, (p^M \mid p \in \Phi))$ and every $t \in T$:*

$$\varphi^T \text{ is true at } t \quad \Leftrightarrow \quad M \models \varphi[t]$$

Kamp's theorem explains why there are only very few important distinct temporal operators for linear time: any first-order definable temporal operator can be expressed using just since and until. We would like to stress here that it would be wrong to conclude from Kamp's result that temporal logic has nothing useful to offer compared to predicate logic. As we pointed out in the introduction, the crucial difference between temporal and predicate logic is that temporal logic is much closer to natural language than predicate logic and, therefore, much easier for people to read and understand. Thus, for the same reason that programming languages such as C or JAVA are not useless just because any program in C or JAVA is equivalent to a Turing Machine, temporal logics do not become useless just because they have the same expressive power as first-order formulae.

Interestingly, the difference between temporal and first-order logic can also be described in technical terms. The translation from first-order predicate logic to temporal logic introduces temporal formulae of non-elementary size (i.e., their size cannot be bounded by a tower of exponentials) [16] and for standard linear time flows the satisfiability problem for temporal logic with S and U is PSPACE-complete (and even coNP-complete with operators F and P only), but it is non-elementary for the corresponding fragment of first-order predicate logic [16, 22, 25].

Kamp's result was the beginning of a long and ongoing research tradition. Results such as Kamp's are nowadays known as *expressive completeness* results. A typical expressive completeness result states that a certain temporal language is equivalent to (some fragment of) first-order predicate logic over a certain class of time flows. For

example, Prior’s original language with the tense operators F and P only and without since and until is expressively complete for the *two-variable fragment* of first-order predicate logic (i.e., first-order predicate sentences using only two individual variables) on arbitrary linear time flows [11, 26]. An overview of recent extensions and variations of Kamp’s theorem is given in [22].

4 Temporal Logic in Computer Science

At this point in our story, computer science enters the scene. A key research topic in computer science is the *correctness problem*: crudely, the problem of showing that computer programs operate correctly [6]. Two key issues associated with correctness are the related problems of *specification* and *verification*. A specification is an exact description of the behaviour that we want a particular computer system to exhibit. Verification is the problem of demonstrating that a particular program does or does not behave as a particular specification says it should.

Temporal logic has proved to be an extremely valuable formalism for the specification and verification of computer systems. This application of temporal logic is largely due to the work of Amir Pnueli, an Israeli logician born in 1941. In 1977, Pnueli was considering the problem of specifying a class of computer programs known as *reactive systems*. A reactive system is one that does not simply compute some function and terminate, but rather has to maintain an *ongoing interaction* with its environment. Examples of reactive systems include computer operating systems and process control systems. Typical properties that we might find in the specification of a reactive system are *liveness* and *safety* properties. Intuitively, liveness properties relate to programs correctly progressing, while safety properties relate to programs avoiding undesirable situations. In a seminal paper [29], Pnueli observed that temporal logics of the type introduced by Prior provide an elegant and natural formal framework with which to specify and verify liveness and safety of reactive systems. For example, suppose p is a predicate describing a particular undesirable property of a program (a “system crash”, for example). Then the temporal formula $G\neg p$ formally expresses the requirement that the program does not crash – this is an example of a safety property.

Thus, Pnueli’s idea was to formally specify the desirable behaviour of a reactive computer system as a formula Ψ of temporal logic. Such a *formal* specification is valuable in its own right, as a precise, mathematical description of the intended behaviour of the program. But it also opens up the possibility of formal verification, as follows. Suppose we are given a computer program \mathcal{P} , (written in a programming language such as PASCAL, C, or JAVA), and a specification Ψ , expressed as a formula of temporal logic. Then the idea of *deductive temporal verification* is to first derive the *temporal theory* $Th(\mathcal{P})$ of \mathcal{P} , i.e., a logical theory which expresses the actual behaviour of \mathcal{P} . The temporal theory $Th(\mathcal{P})$ of the program \mathcal{P} is derived from the text of the program \mathcal{P} . For example, for each program statement in \mathcal{P} , there will typically be a collection of axioms in the temporal theory $Th(\mathcal{P})$, which collectively characterise the effect of

that statement. To do verification, we attempt to show that $Th(\mathcal{P}) \vdash \Psi$. If we succeed, then we say that \mathcal{P} *satisfies* the specification Ψ ; it is *correct* with respect to Ψ . In this way, verification reduces to a proof problem in temporal logic.

Pnueli’s insight led to enormous interest in the use of temporal logic in the formal specification and verification of reactive systems, and ultimately, to software verification tools that are used in industry today. One question that attracted considerable interest in the 1980s was that of exactly what kind of temporal logic is best suited to program specification and verification. Although one can use Prior’s logics for reasoning about programs, they are not well suited to talking about the “fine structure” of the state sequences generated by programs as they execute. For this reason, a great many different proposals were made with respect to temporal logics for reasoning about programs (see, e.g., [24, 3, 35, 42, 1, 10]). In the end, two key formalisms emerged from this debate: *Linear Temporal Logic* (LTL) and *Computation Tree Logic* (CTL). These two formalisms are intended to capture different aspects of computation. LTL describes properties of a single run of a reactive program. Hence it is interpreted over a *linear* sequence of successive machine states. In contrast, CTL describes properties of the *branching* structure of the set of all possible runs of the program.

4.1 From Programs to Flows of Time

Before presenting the semantics of LTL and CTL, let us pause to consider in a little more detail exactly how computer programs give rise to flows of time. Consider the following (admittedly rather pointless) computer program, written in a PASCAL/C-like language.

```
x = y = true;
while (true) do
  if x == false then
    x = true;
  else
    x = false;
  end-if;
end-while;
```

Thus, this program manipulates two Boolean-valued program variables, x and y ; the variable x is initialised to the value `true`, and then its value is subsequently flipped between the values `true` and `false`. The variable y is initialised to `true` and remains unchanged subsequently. Notice that the program never terminates – it is an infinite loop. Now, we can understand the behaviour of this program as a *state transition system*, as illustrated in Figure 1. The state transition graph contains the possible states, or configurations, of the program; edges between states correspond to the execution of individual program instructions. For the program above, there are just two possible system states, labelled s_0 and s_1 . The variables x and y are both true in s_0 , while x is false and y is true in s_1 ; the arrow to state s_0 indicates that this is

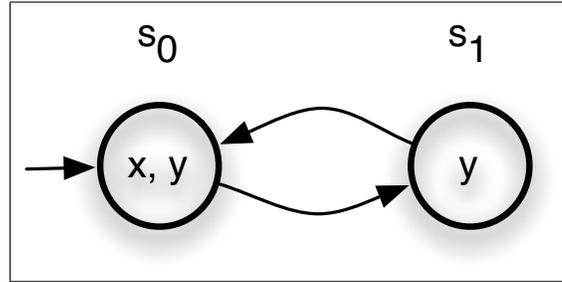

Figure 1: A state transition graph.

the *initial* state of the system. The other edges in the graph indicate that, when the program is in state s_0 , then the only possible next state of the system is s_1 , while when the program is in state s_1 , the only possible next state of the system is s_0 . Now, if we want to reason about the program given above, then we can focus on the state transition graph: this graph completely captures the behaviour of the program.

A little more formally, a state transition system is a triple:

$$M = (S, R, V)$$

where:

- S is a non-empty set of *states*;
- $R \subseteq S \times S$ is a total¹ binary relation on S , which we refer to as the *transition relation*; and
- $V : S \rightarrow 2^\Phi$ labels each state with the set of propositional atoms true in that state.

State transition systems are fundamental to the use of temporal logics for reasoning about programs. To make the link to temporal logic, we need a little more notation and terminology. A *path*, ρ , over M is an infinite sequence of states $\rho = s_0, s_1, \dots$ which must satisfy that $(s_n, s_{n+1}) \in R$ for all natural numbers n . In the program given above, the state transition system is completely deterministic, in the sense that there is only ever one possible next state of the system, and so there is in fact only one path possible through the transition system of the program:

$$\rho : s_0, s_1, s_0, s_1, \dots$$

However, in general, state transition systems are *non-deterministic*, in the sense that, for any given state s_i in the state transition graph, there can be multiple outgoing edges from s_i . This non-determinism can be thought of as reflecting the choices available to

¹By totality we here mean the property that every state has a successor, i.e., for every $s \in S$ there is a $t \in S$ such that $(s, t) \in R$.

the program itself, or as the program’s environment (e.g., its user) interacting with the program. So, in general, there may be more than one possible path through a transition system. The set of all possible paths through a state transition system will completely characterise the behaviour of the program: the paths in a transition system are exactly the possible *runs* of the program. Figure 2 shows how a transition system (Figure 2(a)) can be “unravalled” into a set of paths (Figure 2(b)). Of course, we do not show all the paths of the transition system in Figure 2 – the reader should be able to easily convince themselves that there are an infinite number of such paths, and these paths are infinitely long – even though the transition system that generates them is finite. Now, going back to temporal logic, a path is simply a linear, discrete sequence of time points (now called states), and we can think of such a path as a flow of time, in exactly the way that we discussed earlier. Thus temporal formulae of the kind studied by Prior’s logics can be used to express properties of the runs of programs.

So far, we have three different views of programs: (i) the original program text, written in a programming language like PASCAL or C, above; (ii) the state transition diagram of the program, as in Figure 1 and Figure 2(a); and (iii) the runs obtained from the state transition diagram by “unravelling” it (Figure 2(b)). However, a third view is also possible: we can unravel the transition system into a *computation tree*, as shown in Figure 2(c). The key difference between the logics LTL and CTL is that the language of LTL is intended for representing properties of individual computation paths, while the language of CTL is intended for representing properties of computation trees of the type shown in Figure 2(c).

In the following subsections, we will take a closer look at the technical frameworks of LTL and CTL.

4.2 Linear Temporal Logic – LTL

In this section, we will present and investigate the framework of LTL in a little more detail. In the particular version that we work with, we will only consider temporal operators that refer to the future; it is also possible to consider LTL operators that refer to the past, although we will not do so here [9]. LTL extends classical propositional logic with the unary modal operator X (“next”) and the binary operator U (“until”). Formally, starting with a set Φ of propositional atoms, the syntax of LTL is defined by the following grammar:

$$\phi ::= \top \mid p \mid \neg\phi \mid \phi \vee \phi \mid X\phi \mid \phi U \phi.$$

where $p \in \Phi$. A model for LTL is a path ρ in a transition systems $M = (S, R, V)$. If $u \in \mathbb{N}$, then we denote by $\rho[u]$ the element indexed by u in ρ (thus $\rho[0]$ denotes the first element, $\rho[1]$ the second, and so on). The satisfaction relation “ $\rho, u \models \phi$ ” between between pairs ρ, u and LTL formulae ϕ formalises the condition “after u steps of the computation given by ρ , the formula ϕ holds” and is inductively defined via the following rules:

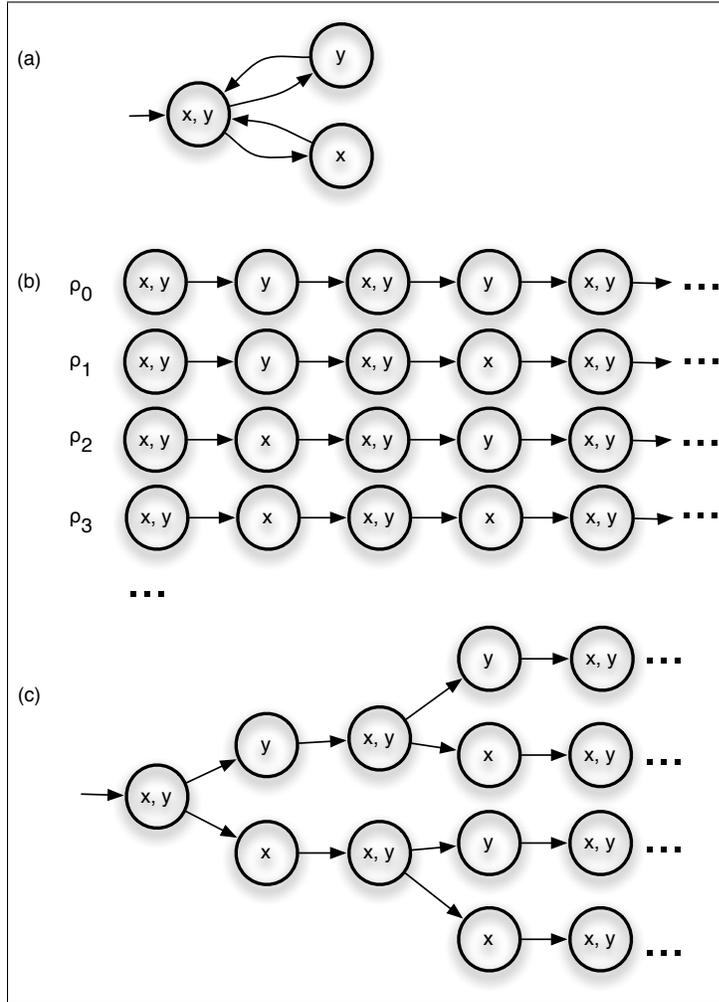

Figure 2: A state transition diagram (a), can be “unravalled” into a set of runs (b), or viewed as a tree-like branching model of time (c).

$$\rho, u \models \top$$

$$\rho, u \models p \text{ iff } p \in V(\rho[u]) \text{ (where } p \in \Phi)$$

$$\rho, u \models \neg\phi \text{ iff } \rho, u \not\models \phi$$

$$\rho, u \models \phi \vee \psi \text{ iff } \rho, u \models \phi \text{ or } \rho, u \models \psi$$

$$\rho, u \models X\phi \text{ iff } \rho, u + 1 \models \phi$$

$$\rho, u \models \phi U \psi \text{ iff there exists } v \geq u \text{ such that } \rho, v \models \psi \text{ and for all } w \text{ such that } u \leq w < v, \text{ we have } \rho, w \models \psi.$$

(It is worth mentioning that the semantics of LTL can equivalently be defined using a flow of time t_1, t_2, \dots and without introducing an underlying transition system M .)

This is the viewpoint taken in our discussion of Prior’s temporal logics. The main purpose of introducing state transition systems is to make explicit the computational interpretation of LTL and to enable the comparison with CTL in the next section.)

The reader will have noticed that the temporal operator U has been given a slightly different interpretation here: previously we had the “strict” interpretation of $\phi U \psi$ according to which $\phi U \psi$ is true at t if ψ is true some time t' later than t and ϕ is true at all time points properly between t and t' . This interpretation is typically seen in philosophical temporal logic motivated by capturing the semantics of natural language tense constructs. In contrast, in typical computer science temporal logic t' can be t itself or later. The same applies to the definition of F and G in terms of U . As before we define the temporal connectives F and G by setting

$$F\phi = \top U \phi \quad G\phi = \neg F \neg \phi.$$

As the truth condition of U has changed, so have the truth conditions of $F\phi$ and $G\phi$. $F\phi$ means “either now or at some time later ϕ ” and $G\phi$ means “now and always in the future ϕ ”. In what follows these distinctions will not play any important role.

Referring back to Figure 2(a), consider the path ρ_0 . The following temporal properties may be seen to hold:

- $\rho_0, 0 \models x \wedge y$
- $\rho_0, 0 \models X(y \wedge \neg x)$
- $\rho_0, 1 \models y \wedge \neg x$
- $\rho_0, 0 \models F(y \wedge \neg x)$
- $\rho_0, 0 \models GF(x \wedge y)$

At this point, let us take a look at the types of properties that LTL may be used to specify. As we noted above, it is generally accepted that such properties fall into two categories: *safety* and *liveness* properties². Informally, a safety property can be interpreted as saying that “something bad won’t happen”. For obvious reasons, safety properties are sometimes called invariance properties. The simplest kind of safety property is *global invariant*, expressed by a formula of the form: $G\phi$. A *mutual exclusion* property is a global invariant of the form: $G(\sum_{i=1}^n \phi_i \leq 1)$. This formula states that at most one of the properties $\phi_i \in \{\phi_1, \dots, \phi_n\}$ should hold at any one time. (The Σ notation is readily understood if one thinks of truth being valued at 1, falsity at 0.) A *local invariant*, stating that whenever ϕ holds, ψ must hold also, is given by the following formula: $G(\phi \rightarrow \psi)$. Where a system terminates, *partial correctness* may be specified in terms of a precondition ϕ , which must hold initially, a postcondition ψ , which must hold on termination, and a condition φ , which indicates when termination

²The material in this section has been adapted from [9, p1049–1054].

Axioms:	
(LAX1)	propositional tautologies
(LAX2)	$\neg X\phi \leftrightarrow X\neg\phi$

has been reached: $\phi \rightarrow G(\phi \rightarrow \psi)$. A *liveness* property is one that states that “something good will eventually happen”. The simplest liveness properties have the form $F\phi$, stating that eventually, ϕ will hold. *Termination* is an example of liveness. The basic termination property is: $\phi \rightarrow F\varphi$ which states that every run which initially satisfied the property ϕ eventually satisfied the property φ , where φ is the property which holds when a run has terminated. Another useful liveness property is *temporal implication*: $G(\phi \rightarrow F\psi)$ which states that “every ϕ is followed by a ψ ”. *Responsiveness* is a classic example of temporal implication: suppose ϕ represents a “request”, and ψ a “response”. The above temporal implication would then state that every request is followed by a response.

A great many technical results have been obtained with respect to LTL. A complete axiomatization was given in [17], and several different axiomatizations have subsequently been presented (see Table 1 for one). Tableau-based proof methods for LTL were introduced by Wolper [43], and resolution proof methods were developed by Fisher [13]. The computational complexity of satisfiability checking for LTL was investigated by Sistla and Clarke, who showed that the problem is PSPACE-complete [36].

One interesting aspect of temporal languages over the natural numbers (and, in particular, LTL) which has turned out to be of great practical and theoretical value in computer science, is the relationship to *automata for infinite words* [28]. Of particular interest in temporal logic are a class of automata known as *Büchi automata*. Büchi automata are those that can recognise ω -regular expressions: regular expressions that may contain infinite repetition. A fundamental result in temporal logic theory is that for every LTL formula ϕ one can construct a Büchi automaton A_ϕ that accepts exactly the models of ϕ (more precisely, the infinite words corresponding to models of ϕ). The technique for constructing A_ϕ from ϕ is closely related to Wolper’s tableau proof

method for temporal logic [43]. This result yields a decision procedure for satisfiability of LTL formulae: to determine whether a formula ϕ is satisfiable, construct the automaton A_ϕ and check whether this automaton accepts at least one word (the latter problem is well-understood and can be solved in polynomial time). We refer the reader to [28] for an overview of automata-based techniques for temporal reasoning.

4.3 Branching Temporal Logic – CTL

If we are interested in the branching structure of reactive programs and their possible computations, then LTL does not seem a very appropriate language. With linear time, there is just one path, so an event either happens or it doesn't happen. But for a reactive program there may be *multiple* possible computations, and an event may occur on some of these, but not on others. How to capture this type of situation? The basic insight in CTL is to talk about possible computations (or futures) by introducing two operators “A” (“on all paths ...”) and “E” (“on some path ...”), called *path quantifiers*, which can be prefixed to a temporal (LTL) formula. For example, the CTL formula AFp says “on all possible futures, p will eventually occur”, while the CTL formula EFq says “there is at least one possible future on which q eventually occurs”. CTL imposes one important syntactic restriction on the structure of formulae: a temporal (LTL) operator must be prefixed by a path quantifier. The language without this restriction is known as CTL* [10]: it is much more expressive than CTL, but also much more complex. For simplicity, we will here stick with CTL.

Starting from a set Φ of propositional atoms, the syntax of CTL is defined by the following grammar:

$$\phi ::= \top \mid p \mid \neg\phi \mid \phi \vee \psi \mid EX\phi \mid E(\phi U \psi) \mid AX\phi \mid A(\phi U \psi)$$

where $p \in \Phi$. Given these operators, we can derive the remaining CTL temporal operators as follows:

$$\begin{aligned} AF\phi &\equiv A(\top U \phi) & EF\phi &\equiv E(\top U \phi) \\ AG\phi &\equiv \neg EF\neg\phi & EG\phi &\equiv \neg AF\neg\phi \end{aligned}$$

As in the case of LTL, the semantics of CTL is defined with respect to transition systems. For a state s in a transition system $M = (S, R, V)$ we say that a path ρ is a *s-path* if $\rho[0] = s$. Let $paths(s)$ denote the set of *s*-paths over M .

The satisfaction relation “ $M, s \models \phi$ ” between between pairs M, s and CTL formulae ϕ formalizes the condition “at state s in the transition system M the formula ϕ holds” and is inductively defined via the following rules:

$$\begin{aligned} M, s &\models \top \\ M, s &\models p \text{ iff } p \in V(s) \quad (\text{where } p \in \Phi); \\ M, s &\models \neg\phi \text{ iff } M, s \not\models \phi \end{aligned}$$

$$M, s \models \phi \vee \psi \text{ iff } M, s \models \phi \text{ or } M, s \models \psi$$

$$M, s \models \text{AX}\phi \text{ iff } \forall \rho \in \text{paths}(s) : M, \rho[1] \models \phi$$

$$M, s \models \text{EX}\phi \text{ iff } \exists \rho \in \text{paths}(s) : M, \rho[1] \models \phi$$

$$M, s \models \text{A}(\phi U \psi) \text{ iff } \forall \rho \in \text{paths}(s), \exists u \in \mathbb{N}, \text{ s.t. } M, \rho[u] \models \psi \text{ and } \forall v, (0 \leq v < u) : M, \rho[v] \models \phi$$

$$M, s \models \text{E}(\phi U \psi) \text{ iff } \exists \rho \in \text{paths}(s), \exists u \in \mathbb{N}, \text{ s.t. } M, \rho[u] \models \psi \text{ and } \forall v, (0 \leq v < u) : M, \rho[v] \models \phi$$

Referring back to the branching time model given in Figure 2(c), we leave the reader to verify that in the initial state, the following formulae are satisfied:

- $\text{EX}x$
- $\neg\text{AX}x$
- $\text{AF}y$
- $\text{E}(xUy)$

At this point, it is a useful exercise to convince oneself that one cannot interpret in any meaningful way LTL formulae in pairs M, s consisting of a model and a state: a run is required to interpret pure temporal formulae without prefixed path quantifiers. Conversely, one cannot interpret CTL formulae in pairs ρ, u consisting of a run and a number: the whole transition system is required to interpret path quantifiers.

Similar to LTL, many technical results have been obtained with respect to CTL. A complete axiomatization is given in Table 2 (the completeness proof and further references can be found in [9]). Satisfiability of CTL formulas is ExpTime-complete.

Similar to linear time temporal logic, the relationship to automata is fundamental for understanding the behaviour of CTL and other branching time logics. Here one employs automata for *infinite trees* rather than infinite words. We refer the reader to [28] for an overview.

5 Interval Temporal Logics

In all temporal logics we considered so far, temporal formulae were evaluated at *time points* or *states*. An alternative, and typically more powerful, way of evaluating formulae is in *intervals*, sets I of time points with the property that if $t_1 < t_2 < t_3$ and $t_1, t_3 \in I$, then $t_2 \in I$. For example, the sentence "Mary often visits her mother" can be true in a certain interval, say from 2006 to 2008, but it does not make sense to say that it is true at a certain time point or state. Many different interval based temporal logics have been introduced [20, 37, 27]. When designing such a language, the first

(BIR2)	From $\vdash \phi$ infer $\vdash AG\phi$

Table 2: A complete axiomatization for CTL.

decision to take is the set of temporal operators. Between time points, there are only three distinct qualitative relations: before, after, and equal. This might be the reason that point-based temporal logics typically employ (some subset) of the rather small set of operators discussed above (Kamp’s Theorem provides another explanation). In contrast, there are thirteen distinct qualitative relations between time intervals, known as Allen’s relations [2]. To give just four obvious examples: interval I can be before interval J (for all $t \in I, t' \in J$ we have $t < t'$), I and J can overlap, I can be during J , and I can finish J . The possible choices of temporal operators for interval-based logics reflect these relations. For example, for the relation ”before” one can introduce a temporal operator $\langle \text{before} \rangle$ whose truth condition is as follows:

$\langle \text{before} \rangle \phi$ is true in interval I if, and only if, there exists an interval J before I such that ϕ is true in J .

Operators $\langle \text{overlap} \rangle$, $\langle \text{during} \rangle$, etc. can be introduced in the same way. The resulting temporal language with operators for all 13 Allen relations (or some subset thereof of equal expressivity) has been investigated extensively [20, 37]. In contrast to most point-based temporal logics, the resulting temporal tautologies are typically undecidable. Often (e.g., for the discrete time flow consisting of a copy of the natural numbers and for the time flow consisting of the reals) they are even not recursively enumerable and, therefore, non-axiomatizable [20]. Such a negative result can give rise to an

interesting new research program: to classify the fragments of the undecidable/non-axiomatizable logic into those that are decidable/axiomatizable and those that are still undecidable/non-axiomatizable. The paradigmatic example of such a program is the undecidability of classical predicate logic that has transformed Hilbert's original Entscheidungsproblem into a classification problem asking which fragments of classical predicate logic are decidable [5]. For interval temporal logics a similar (but smaller scale) program has been launched. The recent state of the art for the classification problem for interval temporal logics is described in [7].

From a philosophical as well as mathematical perspective it is also of interest to regard intervals not as derived objects from time points but as primitive objects [37]. The models in which temporal formulae are interpreted are then not collections of time points, but collections of intervals with temporal relations between them. Typical temporal relations one can consider are (subsets of) the set of thirteen Allen relation, however, now one has to explicitly axiomatize their properties rather than derive them from the underlying point based structure. This then opens the door for representation theorems: when is an abstract structure of primitive intervals representable as a concrete structure of intervals induced by time points? Can one describe those structures axiomatically? We refer the reader to [37, 38] for a discussion of this approach and results.

6 Dynamic Logic

At about the same time that Pnueli was first investigating temporal logic, a different class of logics, also based on modal logic, were being developed for reasoning about actions in general, and computer programs in particular. The starting point for this research is the following observation. Temporal logics allow us to describe the time-varying properties of dynamic domains, but they have nothing to say about the *actions* that *cause* these changes; that is, in the language, we have no direct way of expressing things like "Michael turned the motor on". Here "turning the motor on" is an action, and the performance of this action changes the state of the world. There are many situations, however, where it is desirable to be able to explicitly refer to actions and the effects that they have. One such domain that is particularly well-suited for formal representation and reasoning is computer programs. A computer program can be regarded as a list of actions which the computer must execute one after the other. Note that in contrast to many other domains, there is little or no ambiguity about what the actions are; the computer programming language makes the meaning and effect of such actions precise, and this enables us to develop and use formalisms for reasoning about them. Dynamic logics arose from the desire to establish the correctness of computer programs using a logic that explicitly refers to the actions the computer is executing.

An important question to ask about terminating programs is what properties they guarantee, i.e., what properties are guaranteed to hold after they have finished executing. This type of reasoning can be captured using modal operators: we might interpret

the formula $[\mathcal{P}]\phi$ to mean that “after all possible terminating runs of the program \mathcal{P} , the formula ϕ holds”. Given a conventional Kripke semantics, possible worlds are naturally interpreted as the states of a machine executing a program. However, this modal treatment of programs has one key limitation. It treats programs as *atomic*, whereas in reality, programs are highly structured, and this structure is central to understanding their behaviour. So, rather than using a *single* modal “box” operator, the idea in dynamic logic is to use a collection of operators $[\pi]$, one for each program π , where $[\pi]\phi$ then means “on all terminating executions of program π , the property ϕ holds”. Crucially, π is allowed to contain *program constructs* such as selection (“if”) statements, loops, and the like; the overall behaviour of programs is derived from their component programs. The resulting formalism is known as *dynamic logic*; it was originally formulated by Vaughan Pratt in the late 1970s. Here, we will introduce the best-known variant of dynamic logic, known as *Propositional Dynamic Logic* (PDL), introduced by Fischer and Ladner [12].

Formally, we define the syntax of programs π and formulae ϕ with respect to a set A of atomic actions and a set Φ of propositional atoms by mutual induction through the following grammar:

$$\begin{aligned}\pi &::= \alpha \mid \pi; \pi \mid \pi^* \mid \pi \cup \pi \mid \phi? \\ \phi &::= p \mid \neg\phi \mid \phi \vee \phi \mid [\pi]\phi\end{aligned}$$

where $\alpha \in A$ and $p \in \Phi$.

The program constructs “;”, “ \cup ”, “ $*$ ”, and “?” are known as *sequence*, *choice*, *iteration*, and *test*, and closely reflect the basic constructs found in programming languages:

$\pi_1; \pi_2$ means “execute program π_1 and then execute program π_2 ”;

$\pi_1 \cup \pi_2$ means “either execute program π_1 or execute program π_2 ”;

π^* means “repeatedly execute π (an undetermined number of times)”;

$\phi?$ means “only proceed if ϕ is true.”

Let us see a few examples of PDL formulae, and the properties they capture.

$$p \rightarrow [\pi]q$$

This asserts that if p is true, then after we have executed program π , we are guaranteed to have q true.

$$p \rightarrow [\pi_1 \cup \pi_2]q$$

This asserts that if p is true, then no matter whether we execute program π_1 or program π_2 , q will be true.

The semantics of PDL are somewhat more involved than the logics we have looked at previously. It is based on the semantics of normal modal logic; we have a set S of states, and for each atomic action α we have a relation $R_\alpha \subseteq S \times S$, defining the behaviour of α , with the idea being that $(s, s') \in R_\alpha$ if state s' is one of the possible outcomes that could result from performing action α in state s . Given these atomic relations, we can then obtain accessibility relations for arbitrary programs π , as follows. Let the composition of relations R_1 and R_2 be denoted by $R_1 \circ R_2$, and the reflexive transitive closure (ancestral) of relation R by R^* . Then the accessibility relations for complex programs are defined [21]:

$$\begin{aligned} R_{\pi_1; \pi_2} &= R_{\pi_1} \circ R_{\pi_2} \\ R_{\pi_1 \cup \pi_2} &= R_{\pi_1} \cup R_{\pi_2} \\ R_{\pi^*} &= (R_\pi)^* \\ R_{\phi?} &= \{(s, s) \mid M, s \models \phi\}. \end{aligned}$$

Notice that the final clause refers to a satisfaction relation for PDL, \models , which has not yet been defined. So let us define this relation. A model for PDL is a structure:

$$M = \langle S, \{R_\alpha\}_{\alpha \in A}, V \rangle$$

where:

- S is a set of states;
- $\{R_\alpha\}_{\alpha \in A}$ is a collection of accessibility relations, one for each atomic program $\alpha \in A$; and
- $V : S \rightarrow 2^\Phi$ gives the set of propositional atoms true in each state.

Given these definitions, the satisfaction relation \models for PDL holds between pairs M, s and formulae:

$$M, s \models p \text{ iff } p \in V(s) \quad (\text{where } p \in \Phi);$$

$$M, s \models \neg\phi \text{ iff not } M, s \models \phi$$

$$M, s \models \phi \vee \psi \text{ iff } M, s \models \phi \text{ or } M, s \models \psi$$

$$M, s \models [\pi] \text{ iff } \forall s' \in S \text{ such that } (s, s') \in R_\pi \text{ we have } M, s' \models \phi$$

A complete axiomatization of PDL was first given by Segerberg [34] – see Table 3. The satisfiability problem for PDL is ExpTime-complete. Thus, it has the same computational complexity as CTL. Numerous extensions of PDL with various additional program constructors such as loop, intersection, and converse have been considered. For an overview, we refer the reader to [21]. There also exist first-order versions of dynamic logics in which the abstract atomic actions of PDL are replaced by “real” atomic programs such as, for example, $x := x + 4$ [21].

Axioms:	
(PAX1)	propositional tautologies

7 Further Reading

We emphasise that temporal and dynamic logics are major research areas, with a vast literature behind them. In this short paper, we have been able to do no more than sketch some of the major directions and developments. For more reading, we recommend [41] as a gentle and short introduction to temporal logic, [19] as a mathematical introduction to temporal and dynamic logic, with particular emphasis on the use of such logics for reasoning about programs, and [9] for an excellent technical introduction to LTL and CTL. A recent collection of papers on temporal reasoning in AI is [15]; a comprehensive overview article, providing many pointers to further reading on temporal logic may be found in [14]. The debate on the relative merits of linear versus branching time logics to a certain extent continues today; see, e.g., [39] for a relatively recent contribution to the debate, with extensive references. The definitive reference to dynamic logic is [21].
